TITLE: Structure of the Periphery of Extensive Atmospheric Cosmic Ray  
Showers. (Struktura periferii shirokikh atmosferykh livney kosmi-  
cheskikh luchey, Russian).  
PERIODICAL: Zhurnal Eksperim. i Teoret. Fiziki, 1957, Vol 32, Nr 2, pp 227-240,  
Russian)  
Received: 5 / 1957 Reviewed: 6 / 1957

ABSTRACT: The present paper investigates the spatial distribution of the  
different components of a broad atmospheric cosmic ray shower at  
great distances from its axis (200 - 800 m). For a detailed study  
of this problem the Pamir-Expedition of the Academy of Science of  
the U.S.S.R. (summer and autumn 1950 and 1951) used a new method:  
In different places of the observation plain the flux density of  
all charged particles (and separate from it that of penetrating  
particles) was simultaneously determined with hodoscopic devices.  
(Method of correlated hodoscopes).

Summary of results: The shower domain investigated here consists  
of an electron-photon component and of a penetrating component  
(apparently myons). With increasing distance from the shower axis  
the relative share of the penetrating component increases consider-  
ably and at a distance  $r = 800$  m the flux density of penetrating  
particles and of electrons is equal. The spatial distribution of the

Card 1/2

Structure of the Periphery of Extensive Atmospheric Cosmic Ray Showers.

PA - 2665

total flux density of electrons and of penetrating particles is determined by the formula  $k(r) \sim 1/r^n$  with  $n \sim 2,0$ . On account of the relatively slow decrease of flux densities of shower particles the periphery of the shower plays an essential part in the general balance of the flux of the shower particles. The mechanism of the transition of electrons to the periphery of the shower is reduced to the Coulomb scattering of these electrons by the nuclei of air atoms. The transition of Myons to the periphery of the shower is effected by their Coulomb scattering and also apparently at the expense of the emission angle in the elementary acts of the nucleus cascade process of the positive and negative myons producing these myons. Finally, data on the intensity of primary cosmic particles with extremely high energies of  $10^{16}$  up to  $10^{17}$  eV are given. (10 illustrations)

AUTHORS: Bukatov, V. A., Antonov-Antinov, Yu. N.  
TITLE: A generator of pulse "packets" in the millimicrosecond range  
PERIODICAL: Apparatura dlya yadernoy spektrometrii, no. 1, 1960, 126-132

TEXT: The pulse packets generator described has a pulse repetition frequency of 10 Mc/sec, as it was originally designed for a 256-channel analyzer with this frequency. Other parameters are as follows: Pulse packets repetition frequency:  $2 \cdot 10^3$  cps; range of pulse repetition frequencies within a packets:  $3.75 - 10.25 \cdot 10^6$  cps; pulse height in a packets generator outlet: 0 - 30 v; pulse duration in a packets:  $25 \cdot 10^{-9}$  sec; number of pulses in a packets: 0 - 300. The pulse heights in a packets are constant to 0.5%. The pulse repetition frequency is kept constant by means of a quartz stabilizer. The block diagram is the following:

Card 1/1 3

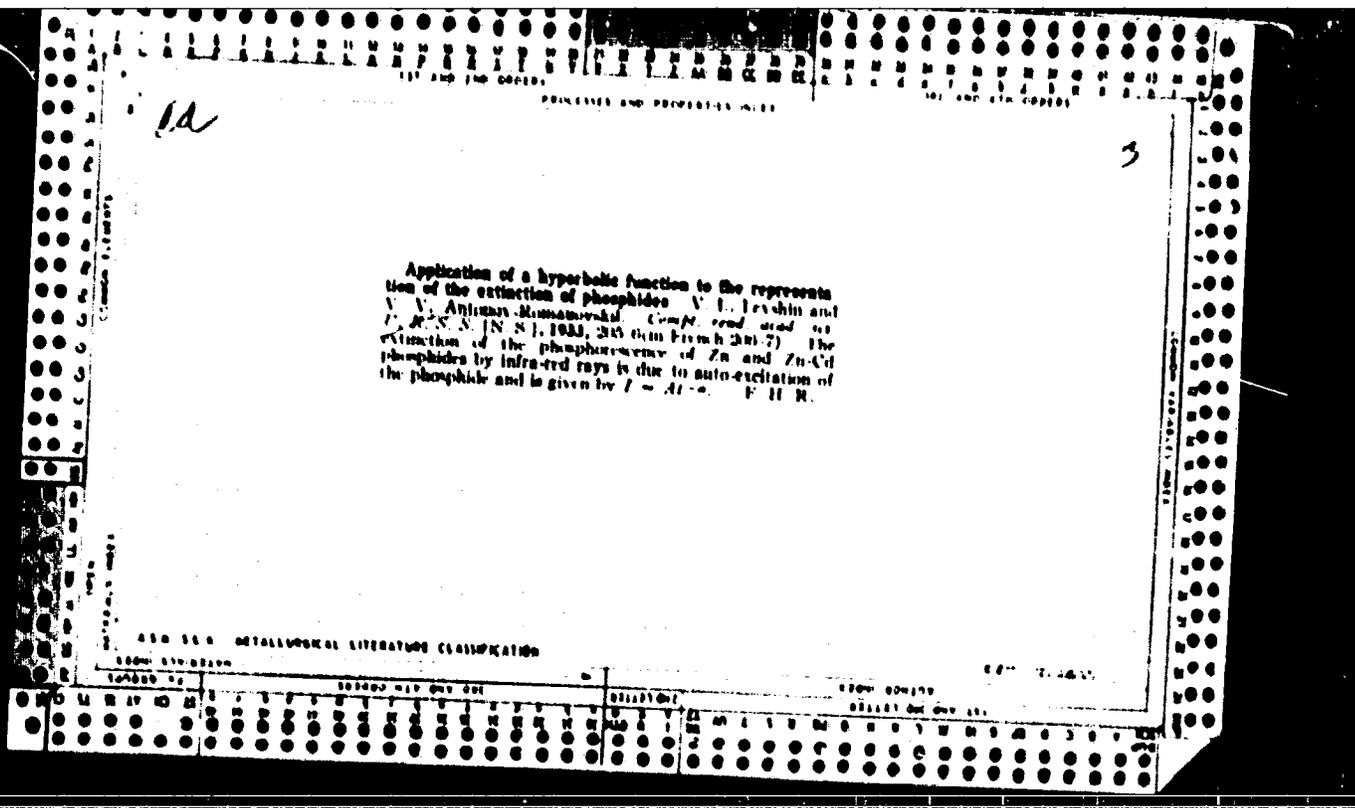

The master oscillator consists of two sinusoidal oscillators and an amplifier-limiter tube. The first of its oscillators operates at 10 Mc and in accordance with B. K. Shembel's design, has quartz stabilization on the tube  $\Pi_1$  (Fig 3) which is of the type 6П14П(6F14P). The second oscillator of the master device works at  $3.75 \cdot 10^6 - 10.25 \cdot 10^6$  cps with a 6P14P tube ( $\Pi_2$  in Fig 3), the amplifier-limiter with a ГУ-29(GU-29) tube ( $\Pi_3$ ) with a + 150 - v supply. Both generators are supplied by pulse transformers with OK-1000(OK-1000) cores. The timing oscillator consists of a blocking oscillator with a 6H3П(6N3P) tube ( $\Pi_4$ ); its pulses have a duration of

Investigations on phosphorescence I. The hyperbolic law of decay of phosphorescence V. L. Levshin and V. V. Antony-Kozmanovskii. *Fiziol. Z. Sovetskii* 3, 790-810 (1954) The hyperbolic equation for the rate of decay of phosphorescence, which holds for only very short time intervals, is transformed to the hyperbolic function  $I = A/(1+t)$ , where  $I$  is the emitted light intensity,  $A$  is a const. numerically equal to  $I$  when the time  $t = 1$ , and a const. characteristic of the rate of decay. Results of measurements with a wire of Zn phosphor, in which the relative intensities were varied 0.001 fold, show the equation to hold over long time intervals during which 75% of the total light stored up in the phosphor is emitted. Self-excitation decreases decay of phosphorescence, the decrease being greater with thicker phosphor layers. II. The quenching of phosphorescence by infra-red rays and its application to photography in the infra-red region of the spectrum. V. L. Levshin, V. V. Antony-Kozmanovskii

and I. A. Tsvetman. *Ibid.* 811-37. The quenching of phosphorescence produced by exposing phosphors to infra-red light of wave length 0.45  $\mu$  is studied. The reciprocity law of Burwin and Rowse is shown to hold, the quenching effect being const. provided the product of the intensity of the quenching infra-red rays and the time of exposure is const. The hyperbolic law of decay of phosphorescence (cf. above) holds for most rate quenching at various wave lengths. The factors influencing quenching which are investigated include: effect of wave length, independence of quenching coeff. and the total light energy of quenching at any one wave length, the relation of the total energy of the quenching light to the quenching, and the relation between the total phosphorescent light emitted and the total quenching light. The quenching coeffs. of 4 phosphors at various wave lengths are plotted to give sensitivity curves resembling those of photographic plates. The application to photography in the infra-red, giving a positive directly, is indicated and photographs taken with 45 sec. exposures at an av. wave length of about 1.0  $\mu$  are shown. R. O. W.

4503. Phosphorescence. Part II. W. L. Lewochin, W. W. Antonow-Romanovsky and L. A. Tamerman, *Phys. Zeits. J. Sowjetunion*, 8 6 pp. 611-627, 1954. In German. The quenching effect of infra-red has been studied. There is no effect on the total light output nor in the law of decay altered in character. It is found that in quenched regions of decay and for not too great a degree of quenching, the law  $L\phi = A\tau^{-1} \ln \phi$  holds, where  $L\phi$  is the remaining light sum in the phosphor and  $\tau$  the light sum of the quenching radiation.  $K$ , the quenching constant is a function of the wave-length of the quenching radiation. The decrease of blackening of a photographic plate produced by the quenching light  $L$  follows the ordinary photographic law of blackening. This offers a possibility of quantitative as well as qualitative infra-red photography. (See preceding Abstract.) J. K.

680. Decay of Phosphorescence of ZnS at Various Temperatures. V. Antonov-Romanovskii. *Comptes Rendus (Doklady) de l'Acad. des Sciences, U.S.S.R.* 17, 8, 77, 83-85, 1937. In French. —Continuing previous work (see Abstract 3144 (1936)) with individual small crystals of ZnS. It has been shown that from 25° to 100° C. the decay follows the law  $I = A/(a + t)^2$  where A, a and are constant, depending on the phosphor. Over this range a is equal to 1.2 but above 147° C. the rate is greater and after a curve in the log I/log t line the value of a becomes 2. These results are not explicable on a simple bimolecular recombination of electrons and ions. As previously explained, however, the simple recombination would be affected by an impoverishment of ions which are nearest to electrons and by a variation of recombination probability with distance between ions and electrons. A study of the curves at the higher temperatures is taken to indicate that the probability of recombination depends on temperature according to  $p_r = p_r \cdot e^{-E_r/RT}$ . An attempt is made to criticize Muto's theory of phosphorescence. J. E.

53, 111 11 1817  
**Mechanism of Luminescence of Alkal-Halogen  
Phosphors.** V. V. Antonov (Kuznetsov). (*Dokl.  
Akad. Nauk SSSR, Ser. Phys.*, 1991, Vol. 3, No. 475,  
pp. 525-531. In Russian with English summary.)  
Discussion of decay phenomena leads to the con-  
clusion that the Shock-Wilson representation of  
semiconductors, if applied to phosphorescence, must  
take account of the interaction between the electron  
and the ionized centre, long before their recombi-  
nation, and also of the fact that the average displace-  
ment of the thermal electron in the time interval  
between captures is relatively small.

Luminescence of phosphors at the moment of excitation. V. P. Litmanov-Lomanovski  
 (Compt. rend. Acad. Sci. U. S. S. R., 1942, 35, 125-129).—On the cessation of  $\text{CaSiO}_3$   
 and  $\text{CaAl}_2\text{O}_6$  powders activated by Mn falls at once to  $\infty$ . The luminescence increases  
 quite smoothly from 0, so that the fall is not explained by the presence of fluores-  
 cence. The kinetics of phosphorescence are examined; the simple black-body theory  
 can account for these results. A limited general comparison with experimental  
 data is given, but this is hindered by experimental difficulties such as the (unknown)  
 quenching properties of the exciting light. J. O'Hara.

Mechanism of the luminescence of phosphors II.  
 V. A. Artyukov-Romanovskii. *J. Phys. (U. S. S. R.)*  
 7, No. 3, 151-67 (1963) (in English), cf. C. A. 37, 613;  
 38, 4190. Theoretical math. A theory of recombi-  
 nation luminescence based on the demonstrated small  
 magnitude (of the order of the lattice constant) of the  
 displacement of a thermal electron in a KCl-Tl phosphor  
 (displacement of a thermal electron is developed, and the  
 between two consecutive trapings and its dependence on the condi-  
 tions of excitation are explained. The magnitude of the  
 diffusion coefficient and of the mobility of electrons is  
 estd. It is shown that a unimolecular decay process  
 and spontaneous recombination in the initial stage are possible.  
 In the KCl-Tl phosphors the luminescence centers are  
 pictured as solid complexes. Excitation raises the electron  
 to a higher level and the center passes to a new state of  
 equilibrium. The energy then released is sufficient to produce  
 complete ionization of the center. Luminescence in the  
 alkali halide phosphors is due to a luminescence center,  
 in the CaS-Ba phosphors to electron transitions from  
 $5d^{10} 4f^1$  levels, in the Zn alkate-Mn phosphors also due to  
 electron transition; in no case is luminescence due to the  
 lattice of the bulk substance, which can influence only the  
 width and shift of the spectrum. P. H. Rothmann

Increase of phosphorescence during excitation. V. V. Antonov-Komarovskii (*Compt. rend. Acad. Sci. GA

Mechanism of phosphorescence. V. V. Antonov-Rumyantsevskii. *Bull. Acad. Sci. USSR, Div. Phys. Chem.* 1958, 10(15). The initial intensity of the emitted light is proportional to the square of the intensity of absorbed light. In the systems  $\text{CaSiO}_3$ , Mn and  $\text{CdH}_2\text{O}$ , Mn the time to reach the max. emission depends on the intensity of the exciting light, another proof of recombination. The decay in the system  $\text{KCl} \cdot \text{H}$  was studied after excitation for 0.8 sec. at variable intensities of exciting light; it is unimol. at the start and bimol. in the later stages. Contrary to the quantum mechanical theory, the electron does not need to be located at defects in the lattice, the mean free path of the "optical" electron being small. ZnS and alk. earth phosphors have decays of different character, attributed to their microcryst. structure and the inhomogeneity of the activator concn. In silicate phosphors the first radiation has an exponential decay independent of temp. or the intensity of exciting light. This is due to the facility with which the electrons arrive at recombination distance from the ions. ZnS-Cu, ZnS-Ag, ZnS-CdS-Ag have hyperbolic decay from the start. ZnS-MnS-Cu emits orange light, which changes to green if the phosphor is irradiated with red light in early stages of decay. This is caused by the presence of independent Mn and Cu centers. The light emission during excitation is increased. 47 references. S. P.

Mechanism of the flash in SrS phosphors activated by rare earth activators and the interaction of activators. V. V. Antonov-Romanovskii, V. L. Levin, Z. L. Mergolitskii, and Z. A. Tyazhenikova. *Izv. Akad. Nauk S.S.S.R., Ser. Fiz.* 13, 75-80(1949); cf. C.A. 43, 11429. Curves of the intensity of stimulated fluorescence as a function of the temp. in SrS activated with Cr, Sm, Eu, Ce + Sm, Eu + Sm show that the max. of 2-activator combinations do not correspond to the curves of 1-activator phosphors and are not linear combinations of single activator systems. Two activators have complex centers contg. both ingredients; thus because of the small concn. chem. forces binding both activators must be postulated. Curves of the spectral emission of these above-named combinations during excitation, decay, and stimulation (flash) show that the sharp Sm lines are absent in stimula-

tion spectra. Same radiation belongs to SrS itself and it is present only in excitation spectra. Stimulation and excitation spectra show at all temps. the characteristic 2-max. curve of Ce; the decay spectra, the 3-max. spectrum of Sm. Fluorescence during excitation of Sm-Eu combinations at different concns. of Sm + Eu show that the spectrum of Eu does not appear until its concn. reaches  $10^{-4}$ ; from then on it appears and the spectrum is modified. In Ce-Sm combinations Ce spectra appear at concns. of  $10^{-4}$  to  $10^{-2}$ ; the Sm spectrum is modified and new lines appear. In stimulated spectra a max. at  $1 \mu$  can be attributed to Sm, a second max. at  $0.6 \mu$  to Ce. This choice is confirmed by the study of phosphors with a single activator. Therefore the stimulation spectrum has a character of additivity (observed also on a SrS-Eu, Ce phosphor). The intensity of decay spectra was measured on single and double combinations shown above at temps. of  $-120^{\circ}$  to  $+20^{\circ}$  and they show the storage of light energy on deep local levels at low temp. and its liberation even with short-wave excitation radiation. The temp. has a considerable influence on the intensity of stimulated radiation because some thermal energy is necessary for the emission of this radiation. The combined centers have a triple function of being centers of emission, of electron localization, and of absorption of the stimulating radiation. S. Pakover

Alkaline earth phosphors, characterized by a high sensitivity to infrared rays. V. I. Levkin, V. V. Antonov-Kuznetsovskii, Z. I. Mogenshtern, and V. A. Trajanzhi. *Zhur. Tekhn. Fiz.* 17, 940 (1947).

Absorption spectra of phosphors of CaS (II), SrS (III), BaS (IV), without activation (I), with Sm (II), with K<sub>2</sub> (III), with Eu (IV), with Ce (V), and with Sm (VI), show that Sm alone causes only a slight shift of the long-wave edge of the absorption band of I to longer waves, only at very high currents of Sm, 0.01 g./g., does it cause narrow absorption bands in the visible. In contrast thereto, Ce gives rise to a new sharp band at 420 m $\mu$ , Eu to continuous absorption beginning at 440 m $\mu$  and extending to shorter waves, V and VI give, resp., the same absorption spectra as III and IV. Consequently, in V and VI, it is Ce or Eu, resp., which is responsible for the absorption. The luminescence spectrum of V has maxima at 440 and 445 m $\mu$ , that of VI at 425 m $\mu$ . Variation of Sm and K<sub>2</sub> Ca causes only shifts in the position and height of the max., without changing the character of the spectrum. Excitation with light absorbed by the host crystal produces all 3 types of emission, namely fluorescence, long-wave phosphorescence, and the flash on irradiation with infrared. If V is excited by light absorbed by the activator (Ce), it shows only fluorescence, excitation of VI by the green light absorbed by Eu produces both fluorescence, phosphorescence, and the infrared-stimulated flash. Whereas Ce and Eu can be termed main activators, Sm plays no significant role in either the absorption leading to excitation or in emission; it decreases

the intensity of the phosphorescence, and, on the other hand, it increases considerably the brightness of the flash. The spectral curve of the yield of the infrared-stimulated flash of V and VI, defined by the ratio of the energy emitted and the infrared energy absorbed, and determined by a procedure taking into account the scattering coefficient and the effective visual sensitivity of the eye, is determined by the host crystal and by Sm, and does not depend on the main activators Ce and Eu. It may mean that the stimulating irradiation is absorbed by Sm centers, then the energy transferred is absorbed by electrons at host levels, and emitted by recombination of excitation of the liberated electrons with ionized centers Ce and Eu. The recombination character of the flash is confirmed by the validity of the hyperbolic decay law  $I = I_0 e^{-t/\theta}$ , and by the parallel dependence of its initial brightness  $I_0$  on the length  $\theta$  of the preliminary excitation. The decay curves, proportional to the no. of ionized centers, are linear from the excitation, in log  $I$  (log  $I_0$ ) coordinates, are parallel and very close to each other. From these curves, the energy stored in V decreases only by 40% on standing at about 20° during the first 5 days, then the decrease becomes even slower. The curve of temp. stimulated emission of V, between 20 and 280°, has only 1 maximum at about 70°, which indicates one single band of deep trapping levels. In contrast to other infrared-sensitive phosphors discussed in the literature, the total output of the infrared-stimulated emission of V is about 5 times greater than the temp. stimulated output. The observed facts lead to the conclusion that the stimulating infrared radiation is primarily absorbed, not by the trapped electrons, but rather by Sm centers. From detns. of the

X

quantum yield of photo-stimulation, assuming  $h\nu$  and over, the no. of repeated trapings of electrons, limited by  $1/\tau$ , cannot exceed a very low. The difference of the total output in infrared and in thermal stimulation may mean that, in the 1st case, electrons fall on the top of the next row, in the 2nd case, on its bottom. Thus

Analysis of decay curves of phosphor powders. V. V. Antonov-Romanovskii and R. S. Krylova. *Zhur. Eksp. Fiz. i Astr. Ser. 19*, 61-74 (1949). -- The proportionality between the initial brightness  $I_0$  and the intensity of excitation  $E$ , over a range of 100 fold variation  $E$ , remains valid for a layer of ZnS + Cu in the form of powder. This indicates that the linear relation  $I_0 = aE$  holds also within each individual grain. In the same range of variation of  $E$ , the total light stored,  $m_0$ , in a thick (0.5 mm) layer of powder, is proportional to  $\sqrt{E}$  at lower  $E$ , but increases progressively slower than  $\sqrt{E}$  as  $E$  increases. In that layer, the proportionality  $m_0 = a\sqrt{E}$  holds only at the very lowest  $E$ , and deviation begins at a very early point. That in a thicker layer this occurs only at substantially higher  $E$ , is due to the fact that the light reaching deeper layers is considerably weakened. At low  $E$ , the relation  $I_0 = \beta m_0$ , where  $\beta_0 = a/\sqrt{E}$ , characteristic of the bimolecular recombination process, remains valid for the powder. However, the kinetic decay curve,  $I$  as a function of time  $t$ , is not a simple 2nd-order hyperbola, but follows, empirically, a law  $I = (a + bt)^{-a}$ , where  $a < 1.5$ . This does not, however, contradict the validity of the 2nd-order hyperbolic decay law for each

nth elementary vol. of the powder. Even if the law does hold for each elementary vol., the overall law,  $I = \sum I_n = \sum (a + bt)^{-a}$ , is different from a 2nd order hyperbola. The explicit confirmation thereof is provided by the fact that a change of  $E$  from  $E_1$  to  $E_2$  shifts the decay curve along the axis of abscissas by  $\Delta \log t = -0.5 \log (E_2/E_1)$ , and along the axis of ordinates by  $\Delta \log I = -0.5 \log (E_2/E_1)$ , i.e.  $\Delta \log I = -0.5 \log t$ . The simple bimolecular law,  $I = a/(a + bt)^2$ , shifts the curve along the axis of abscissas by  $\Delta \log t = -\log (E_2/E_1)$ , and along the axis of ordinates by  $\Delta \log I = -2 \log (E_2/E_1)$ . The rapid slowing down of the increase of  $m_0$  with further increasing  $E$  indicates in the absence of quenching or saturation, an increase of the recombination probability  $\beta$ , and its decrease with  $E$  of the recombination probability  $\beta$ . With  $\beta$  variable, the law of decay for an elementary vol. is no more a 2nd-order hyperbola, but follows  $I = \beta_0/(1 + a\beta_0 t)^2$ . In a general way, relations found with powders may, but need not necessarily, reflect laws valid for an individual elementary mixture. If one excludes improbable or contradictory assumptions, this will be the case only when the decay components are additive. Identification of an overall decay law observed in a powder, with the true decay law, may be misleading. N. Thon

temperature emission of phosphors. V. V. Antouy-Komunovskii (Acad. Sci. U.S.S.R., Moscow). *Doklady Akad. Nauk S.S.S.R.* 68, 487-90 (1940).—The observation that, on heating to higher temps., emission peaks corresponding to the shallower local levels (and appearing at lower temps.) are absent, is usually interpreted on the basis that at higher temps., owing to thermal motion, electrons do not stay at the shallower levels, and, consequently, the light stored in this state is practically zero. This interpretation is erroneous. In a phosphor with 2 kinds of local levels, shallow and deep (subscripts 1 and 2, resp.), with  $n$  = concn. of ionized centers (electrons),  $N$  = concn. of all centers (ionized or unionized),  $n_i$  = concn. of levels,  $\sigma$  = proportional to the effective cross section of recombination,  $\sigma_i$  = proportional to the cross section of trapping at a local level,  $E$  = intensity of the exciting light,  $w_i$  = probability of liberation of a trapped electron, the kinetics of excitation, on the assumption that  $n \ll N$  and  $n_i \ll N_i$  (i.e. electrons fill only a small fraction of the levels) are given by  $dn/dt = \sigma n_0 + KN$  and  $dn_i/dt = -w_i n_i + \sigma_i n_0$  ( $i = 1, 2$ ), with  $n = n_1 + n_2$  and  $n_i = n_{i1} + n_{i2}$  ( $n_{i1} \ll n_{i2} + n_{i1}$ ). For full excitation (stationary state)  $\sigma n_0 = KN$  and  $\sigma_i n_0 = w_i n_i$ , hence  $n_1/n_2 = (\sigma_{21}/\sigma_{12})(w_2/w_1)$ . If the liberation of elec-

trons is purely thermal,  $w_i$  is independent of  $E$ , and  $w_i = w_{i0} e^{-\epsilon_i/kT}$ , where  $\epsilon_i$  = energy of trapping at the local level. It follows that with decreasing temp. the no.  $n_1$  of electrons at shallow levels becomes smaller than the no.  $n_2$  at deep levels. That, however, is the exact reverse of the commonly made assumption. Consequently, the exptl. observation referred to at the outset cannot be accounted for by a purely thermal mechanism of liberation of electrons. Rather, it must be admitted that the absorbed exciting light not only is spent in ionization of light centers, but plays also a role in the liberation of trapped electrons. The probability of optical liberation of an electron is smaller, the shorter the mean thermal life of the electron at that level. Consequently, at room temp., the probability of thermal liberation is predominant at the shallow levels, whereas at the deeper levels the liberation is predominantly optical, and, consequently, independent of  $T$ , and proportional to the exciting light intensity,  $w_i = \sigma_i E$ . This gives  $n_1/n_2 = w_{20}^{-1} \sigma_{21} / \sigma_{12} E$ , i.e.  $n_1$  increases rapidly with decreasing temp., in agreement with expt., whereas  $n_2$  may either remain const. or even decrease. If the shallow levels are more numerous than the deep ones, they may store more electrons, i.e. it is possible  $n_1$  may be larger than  $n_2$ . Then

Change of absorption on excitation of phosphors. L. I. Anikina and V. V. Antony-Kuznetsovskii. *Doklady Akad. Nauk S.S.S.R.* 68, 669-72 (1949).—Excited SrS, CaS, Ce, Sm (I), SrS-Ce, Sm (II), and SrS-Eu, Sm (III) thin layers (50-1 mm), show increased absorption not only in the form of a relatively sharp absorption band at about 1000 m $\mu$ , but also in a broad short-wave region. Thus, the transmittance of excited I is only 70% of that of the unexcited phosphor in the whole range 300-550 m $\mu$ . The increased absorption extends almost over the whole visible region. It behaves as a whole, i.e., the relative change of the absorption, as compared with the unexcited state, is the same in the visible as in the infrared. The dependence of the relative excess absorption on the total light stored  $n$ , investigated for II in 365 m $\mu$ , is roughly linear. This finding provides a rigorous substantiation for the previously established law (C.A. 37, 463) for the rate of annihilation,  $-dn/dt = (\beta + \alpha E)n^2 + EN$ , where  $n$  = concn. of ionized centers (or photoelectrons),  $N$  = concn. of unexcited ionized centers,  $E$  = intensity of the exciting radiation,  $\beta$  = probability of recombination

per unit time at  $n = 1$ . The extra term  $\alpha E n^2$ , without which (i.e. for  $\alpha = 0$ ) the law would go over into a simple 2nd-order bimol. equation, finds a natural interpretation as representing the additional electrons set free by the absorption in the excited state. Comparison of the spectral distribution of the additional absorption with the normal absorption spectrum shows absence of any relation between them; this proves that  $N$  remains practically unchanged on excitation, and confirms the inequality  $\alpha < N$ . The latter means that even on max. excitation, only an insignificant fraction of deep levels is filled with electrons. Spectral sensitivity to a flash goes parallel with the excess absorption. Particularly in the infrared region, at about 1  $\mu$ , only the excess absorption accounts for the flash effect, the normal absorption is inactive in that respect.

**Effect of nonuniformity of excitation on the flash properties of infrared sensitive phosphors.** I. I. Arshina and V. V. Antonov-Romanovskii (Acad. Sci. U.S.S.R.). *Doklady Akad. Nauk S.S.S.R.* 21, 107 (1960); cf. C.A. 64, 938g. The hysteresis consisting in a lag of the intensity  $I$  observed in the flash produced by exposure to infrared, along the branch of decreasing stored light  $n$ , behind the  $I$  observed at the same  $n$  along the branch of increasing  $n$ , i.e. in the course of excitation, may be due to both microheterogeneity of the phosphor, consisting in the presence of centers of different sensitivity to infrared, and to macroheterogeneity, resulting in particular in uneven excitation of different parts of the phosphor. The latter effect was observed on  $\text{SeS}$ ,  $\text{Cu}$ ,  $\text{Sn}$ , with the optimum concentration of activator. A thick specimen showed very broad hysteresis, with  $I$  of the flash along the branch of decreasing  $n$  very much smaller than along the branch of increasing  $n$ . The breadth of the hysteresis loop decreases very markedly in thinner layers, of the order of 0.15-0.20 mm., and is narrowed down still further if the phosphor is excited by illumination with diffuse light from both sides. Under these conditions, the hysteresis all but disappears with a layer  $\sim 0.01$  mm. thick. A simple calculation shows that nonuniform excitation can result in hysteresis only owing to the nonlinearity of the relation between  $I$  and  $n$ .

namely,  $I \sim n^2$ , i.e. because of  $I = -dn/dt$ ,  $I \sim n^2 (1 + \rho n)^2$ . There would be no hysteresis if the law were linear.

Particularities of the luminescence of phosphors. V. V. Antonov-Romanovskii (P.N. Lebedev Phys. Inst. Acad. Sci. U.S.S.R., Moscow). *Zh. Eksp. Teor. Fiz.* 21, 209-73 (1951). --The green luminescent phosphor ZnS (Pb, Cu, in a layer 1 mm. thick, was excited by  $\gamma$ -rays from  $K\alpha$  (about 50 millicurie) at 10 cm. Growth of the luminescence starts not from zero but from a finite intensity  $I_0$ , and the stationary brightness  $I_{st}$  is attained in about 6000 sec. On removal of the source, luminescence falls immediately to a low  $I_1$  which is the initial brightness of the afterglow phosphorescence. As  $I_0 - I_1$  is considerably greater than  $I_0$ , the

excess must be due to practically instantaneous recombination of the high energy electrons which subsist only as long as the  $\gamma$ -excitation is maintained. The total light emitted in natural decay is much smaller than the light stored on 2nd excitation with  $\gamma$ -rays; consequently, in the natural decay, the emission appears to be detd. by recombination of thermal electrons only. Irradiation with infrared, in the presence of the  $\gamma$ -source, produces a flash decaying to a stationary brightness  $I_{st}''$ ; if, at that stage, the  $\gamma$ -source alone is removed, the brightness falls discontinuously to approx. one half. The stationary brightness  $I_{st}'$  is a little greater than  $I_{st}$ , and the light stored in the 1st long excitation with  $\gamma$ -rays,  $N'$ , is a little smaller than the light,  $N''$ , emitted in the infrared flash in the absence of, but after preliminary excitation with  $\gamma$ -rays;  $N' = N'' - \alpha_1$ , the sum of the light emitted in the infrared flash in the presence of the  $\gamma$ -source, and the light emitted after its removal. Evidently, in excitation with  $\gamma$ -rays alone, the light stored is very much greater than in simultaneous exposure to  $\gamma$ -rays and infrared ( $N' \gg \alpha_1$ ), and the fraction of thermal electrons taking part in recombination is much greater, hence  $I_{st} < I_{st}'$ . The kinetics of the decay of  $I$  were detd., at different lengths of excitation  $\theta$ , both in excitation with  $\gamma$ -rays and with light of an intensity so chosen that the brightness of the infrared

flash was approx. the same as on excitation with  $\gamma$ -rays of the same duration of  $\theta$  min. In photo-excitation, doubling  $\theta$  from 0.5 to 1 min. and from 1 to 2 min. doubles the brightness, which indicates unimol. recombination; between  $\theta = 2$  and 1 min., the brightness increases faster than linearly with  $\theta$ , particularly in the initial stages, which corresponds to a bimol. mechanism, and on further increase of  $\theta$  again sets in. A similar behavior is observed in excitation with  $\gamma$ -rays, except that the curves of  $\log I$  as a function of  $\log t$  are steeper. The fact that in the range of larger  $\theta$  where the recombination is predominantly bimol., the ( $\log I, \log t$ ) curves for photo- and  $\gamma$ -ray excitation do not coincide, but intersect, is attributed to uneven vol. distribution of the ionization centers in  $\gamma$ -ray excitation. The difference lies in the capacity of a  $\gamma$ -quantum to ionize a large no. of centers wherever it falls; as a result, ionization centers will be densely distributed along the path of the  $\gamma$ -ray and be absent in the spaces between such channels. At low  $\theta$ , liberated electrons will also be dispersed along discrete nonoverlapping channels, the no. of which will be proportional to  $\theta$ . Further increase of  $\theta$  brings about increasing overlapping of the electron channels, and the recombination will increasingly involve more remote electrons diffusing towards the ionization centers from regions where the latter are absent. One should then expect the sharp difference between the curves of photo- and of  $\gamma$ -ray excitation to vanish increasingly at very long  $\theta$ , where the regions of ionization centers, too, begin to overlap. This was actually observed for very long  $\theta$ . In this range,  $I = At^2$ , i.e. in both photo- and  $\gamma$ -ray excitation, the recombination is purely and simply bimol., as could be expected from an increasing uniformity of the vol. distribution of the ionization centers on longer  $\gamma$ -excitation. Title : Relation between the green luminescence discharge of ZnS-Cu phosphorus and the excitation intensity

Periodical : Dokl. AN SSSR, 96, Ed. 6, 1133 - 1134, June 1954

Abstract : A study of the relation between green luminescence intensity of ZnS-Cu phosphorus and the intensity of the exciting light revealed two types of deviations from the proportionality between these two values. The luminescence intensity during weak excitation increases more rapidly than the proportional intensity of the exciting light. Proportionality exists at a certain interval and further excitation amplification decreases the luminescence intensity of the phosphorus in ratio to the intensity of the exciting light. Powder.** *A. A. Antonov-Romanovskiy* *Zh. fiz. khim.*  
*1954, Vol. 28, No. 4, p. 133-135.*

The diffuse reflectance coefficient is determined as a function of the grain size and the known linear dimensions of the crystallites and the bulk material refractive coefficient. The theory is based on that by Z. Bolek (*Acta phys. hungarica* 1953, Vol. 1, No. 2, pp. 133-135) treats the phosphor layer as a pile of plane parallel homogeneous layers and is developed for crystals of regular and of irregular form, i.e. one in which total internal reflection can occur. The calculated and experimentally determined results are compared and discussed in detail. Actual phosphor layers include crystals of both regular and irregular shape.

ANTONOV - KOMANOVSKIY, V.V.

✓ The dosimetry of radioactive radiations by aid of flashing phosphors. V. V. Antonov-Komanovskii, I. N. Keirim-Markus, M. S. Poroshyn, and Z. A. Trapernikova. *Soviet Phys. Nucl. Sci. Ser. B*, 1955, 342-01 (English summary).—A method of  $\gamma$ -dosimetry is given in which infrared-stimulated phosphors are used, e.g. ZnS-Cu,Pb; SrS-Ce, Sm; SrS-Eu,Sm (I). It was most suitable, therefore it was used to construct a sturdy, portable instrument for the dosage of thermal neutrons,  $\beta$ - and  $\gamma$ -radiation. The work was done mostly with  $\gamma$ -radiation, where the dose was detd. by the brightness of the flash of  $\gamma$ -ray excitation, after the luminescence had been induced with infrared. It showed deep-trap levels and good excitability by hard radiation. This deep-trap level caused a long-time light-sum accumulation up to  $10^4$ , which was the reason why I was selected. The doses registered were between 0.005 and 1000 r. For doses of more than 0.5 r., 2-3 readings were taken. Each reading took about 1/3 min., and there was no relaxation time (delay); the instrument responded spontaneously. The precision was  $\pm 15\%$ ; thus this was not an instrument for research but rather for control. For measurements of  $\beta$ -radiation and of thermal neutron flux the instrument must be shielded with Cd envelopes. W. I.

Title : Luminescence Yield From a System with Three Energy Levels

Orig Pub : Dokl. AN SSSR, 1955, 105, No 1, 50-53

Abstract : The luminescence yield of a system with three energy  
levels is calculated and it permits resolving the fun-  
damental problem of whether the value of the energy yield  
 $\phi$  can exceed unity. Attempts found in the literature  
of a thermodynamic proof of the impossibility of  $\phi > 1$   
are not satisfactory. The energy yield of luminescence  
of a system with three levels (Pringsheim model) (Pring-  
sheim, P., Journal of Physics, 1949, 10, 495) is calcula-  
ted

In detail with allowance for the available thermal radiation in the same way as in the work listed for a system with two energy levels (Referat Zhur Fizika, 1956, 17898, 23129). A rarefied thin layer of luminescent gas is considered, to make it possible to disregard the reverse reaction of the luminescence on the electron transitions of the radiating systems. It is shown that in the anti-Stokes region  $\eta$  can be greater than unity and that this does not contradict the second law of thermodynamics. The energy of a luminescent body together with the excitation energy is transferred to the surrounding medium, the temperature of which is lower than the temperature of the exciting body. This, as indicated by Pringsheim, is analogous to the action of refrigerator. It is shown that it is possible to have "negative" luminescence, i.e., not an excess above the background of thermal radiation, but a deficiency of radiation, having a finite duration.

 Title : Production of Resonance Fluorescence of Atoms.  
 Orig Pub : Zh. Eksperim. i teor. fiziki, 1955, 28, No 2, 253-254

Abstract : Production of photoluminescence is given by the expression:  $q = \frac{a}{(A + B_0)n_2 - B_0n_1} / B_0(n_1 - n_2)$ , where  $a$  is

density of energy of exciting light,  $(A + B_0)n_2$  is complete number of quanta radiated in unit of time,  $B_0n_1$  is the number of quanta of black radiation absorbed by the system in unit of time. Denominator shows absorbed surplus of radiation over the background of black radiation. For the quantum production of fluorescence we obtain the expression:

$$q = 1 / \left\{ 1 + (a_0/A) [1 - \exp(-h\nu/kT)] \right\}. \text{ Quantum production}$$

**Title** : Decrease in the illumination yield of phosphors during intense excitation

**Periodical** : Zhur. eksp. i teor. fiz., 29, No 6(12), Dec 1955, 830-833

**Abstract** : A demonstration that the decrease in the illumination yield of phosphors ZnS-Cu and ZnS-Cu,Co during intense excitation is due in considerable degree to the light-eliciting action of the exciting light and to the fact that recombination of optical electrons or "holes" leads to radiatorless transitions. The authors show that the same causes lead to the fact that the light sum determined from the curve of illumination growth turns out to be considerably less than the light sum determined from the curve of extinguishing. They conclude that the causes for the decrease in the light yield of the phosphor ZnS-Cu,Co outside the region of the so-called plateau are the same as for the phosphor ZnS-Cu, and that for small intensities of the exciting light this decrease is caused by the increase in the role of external extinguishing, while for large intensities it is due to the light-eliciting action of the exciting light. The authors remark that incorrect interpretations of results in studies of extinguishing of ZnS-Cu phosphors by ferrous elements are caused by neglect of phenomena connected with the light-eliciting action of the exciting light. Title : Nature of Luminescence Losses of ZnS-Cu, Co Phosphor in the Region where Output is Independent of Exciting Light Intensity.

Orig Pub : Optika i spektroskopiya, 1956, 1, No 1, 66-70

Abstract : Investigation of correlation between quantum yield  $q$ , of ZnS-(Cu, Co) phosphor, and the intensity  $E$  of exciting light. The results are analogous to those obtained with pure ZnS-Cu phosphors (RZhKhim, 1955, 23171) with the difference that in the "plateau" region  $q \ll 1$ , whereas in the case of ZnS-Cu  $q \approx 1$ . It was found that decrease of  $q$  in the presence of Co is due to recombination of free holes with localized electrons. The relative proportion of these recombinations increases sharply after ionization due to the formation of deep electron traps by the cobalt.

Title : Kinetics of the Glow of the ZnS-Cu, Co Phosphor in the Region where the Glow Yield is Independent of the Intensity of the Exciting Light.

Orig Pub : Optika i spektroskopiya, 1956, 1, No 1, 71-76

Abstract : Continuing their work, (see Abstract 2361), the authors show that the inequality of the light sums, computed from the curves for the flareup and extinction of the glow, observed in the region where the glow yield is independent of the intensity of the exciting light ("plateau" region) for the ZnS-Cu, Co phosphor, is caused by the change in the distribution of electrons and the holes over capture levels of various depths, occurring during the time of the flareup. The temperature shift of the "plateau" region was used to estimate approximately the depth of the deepest electron and hole traps  $\epsilon^-$  and  $\epsilon^+$ . The results were:  $\epsilon_{Cu}^- \approx \epsilon_{Cu}^+ \approx 0.33 \text{ ev}$ ,  $\epsilon_{Cu, Co}^- \approx 0.35 \text{ ev}$ ,  $\epsilon_{Cu, Co}^+ \approx 0.44 \text{ ev}$ . Since  $\epsilon_{Cu, Co}^- \approx \epsilon_{Cu}^-$ , the deepest hole-capture levels are the same in the ZnS-Cu and ZnS-(Cu,Co) phosphors. Apparently these levels are the unionized glow centers of Cu. The reduction in the luminescence yield outside the "plateau" in the case of weak excitation is attributed to the increase in the role of the relatively small amount of particularly deep electron and hole traps, which increase sharply the fraction of the non-radiating recombinations.

**TITLE:** On a Theoretical Derivation of the Decay Law of Luminescence for the Case of Resonance Quenching.  
(O teoreticheskom vyvode zakona zatukhaniya lyuminestsentsii pri rezonansnom tushenii.)

**PERIODICAL:** Optika i Spektroskopiya, 1957, Vol.III, Nr.4.  
pp.389-391. (USSR)

**ABSTRACT:** B. Ya. Svoshnikov (Ref.1) criticised a theoretical derivation of the decay law of luminescence in the case of concentration (or more generally, resonance) quenching given in Refs. 2, 3 by Förster and Galanin respectively. These criticisms of Svoshnikov are based on a misunderstanding. The present authors derive the decay law in greater detail. The present derivation is based on a method proposed by one of the authors (Ref.4). It is assumed here that luminescent quenching in solution occurs due to induction-resonance transfer of the excitation energy from the excited to non-excited molecules. If viscosity of the medium is sufficiently great to neglect

Card 1/4

the Case of Resonance Quenching.

decay law - (Eq.6 on p. 390)

$$n(t) = n_0 e^{-\frac{t}{\tau_0} - 2q\sqrt{\frac{t}{\tau_0}}},$$

where  $q$  is a constant which depends on  $R_0$ , and  $R_0$  is a constant which depends on the properties of interacting molecules;  $\tau_0$  is the average lifetime of the excited state in absence of quenching. The decay law quoted above (Eq.6 on p.390) is identical with that obtained by Förster (Ref.2). The authors deal also with Sveshnikov's criticisms of Förster's work. In particular the authors show that Sveshnikov's formula given by Eq.8 in the present paper is identical with Förster's formula, given by Eq.7 on p.391, when the number of excited molecules at zero time is sufficiently large. There are 4 references, 3 of which are Slavic.

TITLE: On the Diffusion Theory of Phosphorescence.  
(O diffuzionnoy teorii fosforestsentsii.)

PERIODICAL: Optika i Spektroskopiya, 1957, Vol.III, Nr. 6,  
pp.592-601. (USSR)

ABSTRACT: A theoretical paper. The present author has shown earlier (Refs.1,2) that, if the mean free path of an electron in the conduction band is of the same order as the lattice constant, then the kinetics of phosphorescence decay may be described by a linear diffusion equation (Eq.2 on p.592) which takes into account attraction of electrons by ionized centres. The author applies this equation to the case of a phosphor which has electron traps of only one type (one depth), when the probability of repeated capture of electrons is much higher than the probability of their recombination, and only a small proportion of traps is filled with electrons. This case is mathematically equivalent to the case when traps of several types are present but the electron distribution in them does not change during phosphorescence decay.

TITLE: New Results in the Field of Phosphorescence Investigations  
(Novyye rezul'taty v oblasti issledovaniya fosforestsentsii)

PERIODICAL: Izvestiya Akademii Nauk SSSR, Seriya Fizicheskaya, 1957, Vol 21,  
#4, pp 484-493 (USSR)

ABSTRACT: There are three main lines of investigations in the study of  
luminescence of crystallophosphors:

1. The study of the nature of luminescence and capture centers.
2. The study of luminescence kinetics, and
3. The study of energy balance.

The nature of luminescence and capture centers.

Krivoglas (2) investigated the shape and temperature-dependence of absorption bands and luminescence of impurity centers. Theoretical results agree well with experimental data.

Two directions in studying the nature of luminescent centers are developed in the Soviet Union: the first, founded by

Card 1/4

48-4-3/48

TITLE: New Results in the Field of Phosphorescence Investigations  
(Novyye rezul'taty v oblasti issledovaniya fosforestsentsii)  
haloid phosphors by the author (17).

There are new results in determination of localization energy of electrons and holes. Lushchik (4) developed a new method of thermal decolorization.

Bohun and Lepper (19) discovered independently a close connection between the course of thermal emission and the course of thermal de-luminescence curve. Peaks in one curve correspond to peaks in the other under uniform heating of the phosphors.

Eliashberg (21) showed that the curves of brightness fading differ in shape from the second-order hyperbolas, especially in the beginning.

Energy balance in luminescence.

The yield  $q$  in recombination luminescence as a rule depends on the intensity  $E$  of exciting light. Alentsev et al. (22) found for the ZnS-Cu-phosphor that  $q$  is constant for medium  $E$  and has a maximum value which then falls off to both sides.

Card 3/4

Similar experiments were carried out by Vinokurov and

48-4-3/48

**TITLE:** New Results in the Field of Phosphorescence Investigations (Novyye rezul'taty v oblasti issledovaniya fosforestsentsii) author (23) for the ZnS-Cu, Co-phosphor at various temperatures.

Vinokurov and Fbk (25) showed for ZnS-Cu and ZnS-Cu, Co phosphors that some regularities in yield reduction at a decrease of exciting light intensity could be explained by the mechanism of external quenching.

The problem of sensitization of luminescence is closely connected with the yield problem. Some results secured by Shchukin (26) in his experiments indicate the existence of sensitization process.

PERIODICAL: Optika i Spektroskopiya, 1958, Vol 5, Nr 4, p 484 (USSR)

ABSTRACT: Complete translation. F.I. Vergunas and L.R. Krasovskaya state in their paper "Decay of afterglow of ZnS-Cu phosphors in  $\log I$ ,  $\log t$ , and  $\log I$ ,  $\log (1 + pt)$  coordinates" that my criticism (Ref 1) of E.I. Adirovich's decay theory (Ref 2) is unfounded. These authors write: "comparison of theory with experiment, made in Ref 2 (i.e. in my critical note - V.V. A.-R.) is not correct". In my criticism of Adirovich's book I used only those experimental results which were used by Adirovich himself to show that his calculations were correct. I showed, in the same way as it was done by Vergunas and Krasovskaya, that comparison given by Adirovich is incorrect. Vergunas and Krasovskaya also say: "in experiments one should use, if possible, an "ideal model" for which this law was obtained". I did show in my criticism that Adirovich's error consists in his statement that his calculations are applicable to real phosphors which are not

Card 1/2

On the Paper of F.I. Vergunas and L.R. Krasovskaya

SOV/51-5-4-21/21

special cases. I conclude that Vergunas and Krasovskaya came finally to the same conclusion which I reached several years ago. It is not clear, however, why they apply their criticisms to me and not to Adirovich (the decay formula of Adirovich was also deduced by Allickson and Parker (Ref 3)). References: (1) V.V. News in Brief. International Conference on the Physics and Chemistry of Crystal Phosphors

PERIODICAL:

Vestnik Akademii nauk SSSR, 1959, Nr 10, p 87 (USSR)

ABSTRACT:

This conference was organized by the Subcommittee for Luminescence of the Department of Physical Sciences of the German Academy of Sciences in Berlin and the Institute of Physical Chemistry of E. M. Arndt University and held at Greifswald (Eastern Germany) from April 26 to April 29, 1959. Scientists from the Soviet Union, Hungary, Poland, Czechoslovakia, France and Switzerland participated. G. Witzmann and G. Ortman and collaborators (Eastern Germany) reported on some properties of phosphors. K. B. Bar (Eastern Germany), V. Ya. Oranovskiy, B. A. Khmelinin (USSR) and Z. Bodo (Hungary) spoke about the electroluminescence of various monocrystals. A. Bohun (Czechoslovakia), Ch. B. Lushchik (USSR) dealt with alkali haloid compounds of phosphors. Moreover, the reports by A. Balarin, K. Friedrich and L. Herfors (Eastern Germany) and P. Jaszozin (Poland) are mentioned here. The author of the present paper spoke on the kinetics of the annealing of phosphors under special conditions. ✓

TITLE: On Relaxation of Electroluminescence After Small Departures From the Steady State (O relaksatsii elektroluminesentsii pri malykh otkloneniyakh ot statsionarnogo sostoyaniya)

PERIODICAL: Optika i Spektroskopiya, 1959, Vol 6, Nr 2, pp 229-231 (USSR)

ABSTRACT: An electroluminescent system sooner or later relaxes to its steady state. For small initial departures of the system from its steady state the author calculates relaxation curves in their most general form, i.e. not considering the nature of the electroluminescent emission mechanism. He obtains, inter alia, a formula which gives the difference between the excited ( $n$ ) and steady state ( $n_0$ ) electron densities.

$$\Delta n = n - n_0 = \Delta n_0 e^{-\frac{t}{\tau}} \quad (7)$$

where  $\Delta n_0 = \Delta n$  at time  $t = 0$ ,  $\mu$  is a positive non-dimensional constant, and  $\tau$  is the excited-state lifetime. Using Bukke, Vinokurov and Fok's data on electroluminescence relaxation in the ZnS-Cu,Cl phosphor (Ref 1), the author calculated, using his own theoretical formulae, the value of  $\tau$ . This value was found to be 7-16 sec in the presence of an electrical field, compared with  $\tau \sim 0.5$  sec measured directly during relaxation (no electric field) by Bukke et al. (Ref 1). This

Card 1/2

SOV/51-6-2-16/39  
On Relaxation of Electroluminescence After Small Departures From the Steady State

discrepancy may be due to an increase of the electron energies produced by the applied electric field. The effective recombination cross-section of electrons decreases strongly with their energy and consequently the electron lifetime is lengthened. Acknowledgments are made to M.V. Fok for his advice. The paper is entirely theoretical. There are 3 Soviet references.

TITLE: The Initial Stages of Decay in Phosphors with Levels of Several Types

JOURNAL: Optika i spektroskopiya, 1969, Vol 7, Nr 3, pp 376-383 (USSR)

ABSTRACT: The author considers decay of phosphorescence in the presence of levels of several types. The problem is very complex because of non-linearity of the corresponding kinetic equations. It is shown that, under certain conditions, the decay curve in the initial stages can be represented as a sum of exponentials provided that the probability of repeated capture of free charges is higher than the probability of their recombination with localized charges and provided there is no saturation. The paper is entirely theoretical. There are 3 Soviet references.
